Physical clock synchronization : NTP.

clock synchronization is done by two methods:

1. Internal synchronization.
2. External synchronization.

External synchronization.

* External synchronization refers to synchronization of process clock c_i with an authorize external source S . Let $D > 0$ be the synchronization bound and S be the source of UTC.

* We say that clocks c_i are accurate within the bound of D .

Internal synchronization.

* Let $D > 0$ be the synchronization bound and c_i and c_j are clocks at processes P_i and P_j respectively

* Then $|c_i(t) - c_j(t)| < D$ for $i, j = 1, 2, \dots, N$ and for all real times t . we say that clocks c_i, c_j agree within the bound of D .

Clock correctness.

- * A hardware clock, H is said to be correct. if its drift rate is within a bound $P > 0$.
- * Interval: $(1-P)(t'-t) = H(t) - H(t) = (1+P)(t'-t)$
(where $t' > t$)
- * A faulty clock is one that does not obey the correctness condition.
- * A clocks crash failure is said to occur when the clock stop ticking altogether.

Synchronization in a synchronous System.

- * A synchronous distributed system is one in which the following bounds are defined:
 - Time to execute each step of a process.
 - Each message transmitted over a channel.
 - bounds: Each process has a local clock whose drift rate from real time has a known bound.

* $\epsilon = (min + max) / 2$ and receivers clock = $t + (min + \epsilon)$

Cristians Method for Synchronizing clocks

The clock requests time and synchronizes only if the round-trip is within a certain

Cristians Algorithm.

- * Christian algorithm is centralized passive time server type algorithm.
 - * Assumptions: There is a machine with WWW receiver, which receives precise UTC.
- It is called the time server

Algorithm.

- * A Machine sends a request to the time server at least every $d/2r$ seconds, where d is the maximum difference allowed between a clock and the UTC.

Current time :-

Time stamp:

$$T_{new} = T_{server} + (T_0 + T_1) / 2$$

Adjust the clock.

- * If the clock is faster than the UTC, add less to the time memory.
- * If the local clock is slower than the UTC, add more to the memory for each clock.

Berkeley Algorithm

Time server is a active machine

- * The server polls each machine periodically, asking it for the time.

- * Instead of sending the updated, time back to the slaves, which would introduce further uncertainty due to network delays.

- * Each of these machines sends a timestamp as a response to the query.

Network Time Protocol.

- * Cristian's method & the Berkeley algorithm are intended for intranets.
- * The Network Time Protocol (NTP) is yet another method for synchronizing clocks that uses a hierarchical architecture. Where the top level of the hierarchy are servers connected to a UTC time source, such as a GPS Unit.

Network time protocol goals:-

- * Multicast on high speed local LANs.
- * Procedure call mode
- * symmetric mode.

Features of NTP.

1. Multicast
2. Procedure-call.
3. Symmetric mode.

Multicast mode:

- * high speed LAN
- * LAN.

Procedure mode:-

- * Operations of Cristian's algorithm.

symmetric mode!

Symmetric mode is intended for servers that

Snapshot Algorithms for FIFO channels.

Candy-Lampert algorithm.

- * Candy-Lampert algorithm records a set of process and channel states such that the combination is a consistent global state. Communication channels assumed to be FIFO.

Assumptions.

- * The Candy-Lampert algorithm uses a control message, called a marker whose role in a FIFO system is to separate messages in the channels.

Algorithm:-

1. Initiator process P_0 records its state locally.
2. Marker sending rule for process P_i :

After P_i has recorded its state, for each outgoing channel Ch_{ij} , P_i sends one marker message over Ch_{ij} .

2. Marker receiving rule for process P_i :

Process P_i on receipt of a marker over channel Ch_{ji} .

If (P_i has not yet recorded its state) it

Records its

Records the state of

3) Message-Passing System System versus Shared Memory Systems.

Message-Passing

- * Two Processes communicate with each other by passing messages. (Direct and Indirect)
- * Message Passing used as a method of communication in microkernels.
- * Send
- * Receive.

Shared Memory

- * Shared memory systems are those in which there is common shared address space data variables, for synchronization among the processor.
- * Shared memory allows maximum speed and convenience of communication, as it can be done at memory speed
- * Shared memory is faster than message passing.

Emulating Passing on a shared memory

- * Synchronization Primitives like write and read operation are controlled by sender/receiver processor.

- * Message passing can be emulated by P_i to the mail box of P_j from the mail box of P_j .

starts Recording messages arriving Over other incoming channels.

else (P_i has already recorded its state).

P_i records the state of C_{ji} as the set of all messages it has received Over C_{ji} since it saved its state.

Property of the Recorded Global State.

- * The recorded global state may not correspond to any of the global states that occurred during the computation.
- * Each process records its own state, and the two processes that a channel is incident on cooperate in recording the channel state.
- * On receiving the marker, q records its state, which is D , and records the state of c to be the empty sequence.
- * On receiving the marker, p records the state of c' as the sequence consisting of the single message M' .
